Abstract: *Natural Language Processing* (NLP) is one of the major branches in the emerging field of *Artificial Intelligence* (AI). Classical approaches in this area were mostly based on parsing and information extraction techniques, which suffered from great difficulty when dealing with very large textual datasets available in practical applications. This issue can potentially be addressed with the recent advancement of the *Deep Learning* (DL) techniques, which are naturally assuming very large datasets for training. In fact, NLP research has witnessed a remarkable achievement with the introduction of *Word Embedding* techniques, which allows a document to be represented meaningfully as a matrix, on which major DL models like CNN or RNN can be deployed effectively to accomplish common NLP tasks. Gradually, NLP scholars keep developing specific models for their areas, notably attention-enhanced BiLSTM, Transformer and BERT. The births of those models have introduced a new wave of modern approaches which frequently report new breaking results and open much novel research directions. The aim of this paper is to give readers a roadmap of those modern approaches in NLP, including their ideas, theories and applications. This would hopefully offer a solid background for further research in this area.

Keywords: Natural Language Processing, Artificial Intelligence, Deep Learning, Word Embedding, CNN, RNN, LSTM, Sequence-to-sequence, Language Model, BERT.

1. Introduction

Natural Language Processing (NLP) [1] is one of major branches of *Artificial Intelligence* (AI) [2], which focuses on applications based on human natural languages. The crucial challenge of this area lies on the "process" to understand the meaning of human language. In this context,

https://doi.org/10.25073/2588-1086/vnucsce.302

the term "process" can be understood as a way to transform from a presentation into another one. In that case, written or spoken language forms will be processed to be transformed into a formalism understandable by computers. Typically, major tasks of NLP include the following.

- *Text Classification* [3]: It can be considered as one of the most popular tasks in this area. In this task, a document will be classified into a predefined category. For instance, Google's e-mail system can classify if an incoming e-mail is a spam or not.

- Sentiment Analysis [4]: It aims to analyze the sentiment of the author/writer of a textual document (normally positive, negative or neutral). This task can be considered as a specific kind of text classification applications where each sentiment value is a category. This task is very useful for e-commerce systems nowadays, where reviews of customers can be analyzed to help a brand to obtain the opinions/feedback of users over their products.

- *Entity Recognition* [5]: This aims to recognize entities mentioned in a document. In practical applications, those entities are *named* and usually belong into a certain class.

- *Topic Modeling* [6]: In this context, a topic is considered as a set of relevant keywords, which can provide hint to a certain concept. For example, the set of words *football*, *stadium*, *trekking*, *swimming* can imply the concept, or topic, of *sport*. The aim of this task is to detect possible topics mentioned in a document by means of finding sets of relevant keywords. In order to fulfill this, the Topic Modeling technique is needed to be trained with a very large corpus in order to evaluate the cooccurrence probability of words potentially belonging to a same topic.

- *Machine Translation* [7]: Sometimes referred to by the abbreviation *MT*, this task aims to automatically translate a document from one language into another.

- *Chatbot* [8]: Ideally, this is an interactive system which can communicate with users using natural languages without human interference.

Nowadays, this kind of application has been increasingly attracted much attention from enterprises in various domains.

- Automatic Summarization [9]: This task aims to produce a shortened version of a document, which captures major important points of the original text using a coherent natural language. This task is highly practical today to help human to extract useful information from large textual datasets from various domains.

Typically, the classical approaches for NLP normally combine syntax analysis and information extraction where documents are represented as vectors, e.g T F-IDF of bag-of-words ones. With the rapid development of computational resources since the end the 20th century, Deep Learning (DL) technique has been deployed effectively to handle various problems of computer science, including NLP. Once applied to solve NLP tasks, the applications of Deep Learning have achieved some remarkable milestones as illustrated in Figure 1. Since the application of neural language model was reported in 2001, perhaps the first notable milestone of NLP in this direction is the introduction of Word Embedding in 2013. This technique allows encoding each word in a document into a numerical vector, which is interpreted from the contexts that this word is likely to appear in a training corpus. Thus, a document can be represented as a matrix or an ordered set of vectors, on which typical deep learning architectures such as Convolutional Neural Network (CNN) or Long Short-Term Memory (LSTM) can be effectively deployed. Especially, an architecture combined from two opposite (forward and backward directions) LSTM models, known as Bidirectional LSTM, or BiLSTM, had also become popular for NLP tasks due to its ca-pability of capturing information a documents in both opposite directions in a document.

After some initial success gained by those models on NLP tasks, the research community continued witnessing the births of some textoriented advanced techniques including *sequence-to-sequence* (or *seq2seq*) architecture in 2014 and *attention mechanism* in 2015. In 2018, the use of pre-trained language models such as *Transformer*, *BERT* or *GPT* marked some significant improvements on performance of NLP tasks, which has still been adopted until today.

In this paper, we review the modern approached in NLP related to the above discussed research. Firstly, we present popular pipelines for processing data in NLP tasks, including both classical and DL-based ones. Next, we present the Word Embedding techniques, followed by remarkable achievements of DL-based ressearch for NLP. They include using Convolutional Neural Network (CNN) for feature extraction; the models based on *Recurrent Neural Network* (RNN) to handle sequence data; the sequence-tosequence model and attention mechanism; the transfer learning technique withs pretrained language models. Finally, the paper concludes with some discussion about some most recent results and directions in this area.

It is also noted that the work presented in this paper aims to give readers an overall picture of the modern approaches in NLP at a foundation level. Interested readers can further refer to more intensive surveys given in [10-13].

2. Processing Pipelines of NLP Applications

Like other data processing applications, NLP applications are usually developed on top of a *pipeline* to process data step-wise. In this section, we discuss two typical pipelines mostly used in classical and DL-based NLP applications.

2.1. The Classical NLP Pipeline

In traditional approach, NLP consists of two main steps described in Figure 2. The first step is referred to as *Pre-processing*, which filters out redundant information and standardizes input text into a common format. Typical pre-processing actions includes *tokenization*, *stemming*, *stop word removal* and *Part-of-Speech (PoS) tagging*.

Figure 2. Classical NLP pipeline.

The next step is called *Modeling*, which is in charge of introducing a model solving the intended tasks with three operations as follows.

The next step is called *Modeling*, which is in charge of introducing a model solving the intended tasks with three operations as follows.

- *Feature Extraction*: In machine learning, data is represented as features. Feature extraction process is of building feature set and filtering out important features that best represent input data. In terms of textual data, *bag-of-words* (BOW) [14] or *TF-IDF* vectors [15, 16] are common features.

- *Model Construction*: Model is the result of applying appropriate machine learning algorithms on input data. Traditional NLP approaches make use of supervised learning techniques including SVM [17, 18], NB Classifier [19] or MLP [20], and unsupervised methods such as clustering [6] or LDA [6, 21] to construct models.

- *Outcome Inference*: This is to apply the trained model on data to obtain the final results.

2.2. The Deep Learning-based NLP Pipeline

Figure 3. DL-based NLP pipeline.

With the rising of Deep Learning, traditional NLP approaches are now gradually replaced by deep learning models. Though many highly complicated deep learning models are built for different NLP tasks, they basically follow the same pipeline described in Figure 3, which is carried out by the following operations.

- Similar to the classical pipeline, the raw textual data are firtsly pre-processed with the common modules of tokenization, stemming, stop word removal, etc.

- Data representation is essential in deep learning architectures. Different from traditional approaches which make use of document-level information, modern models use embedding layer to transform words or even characters into numerical vectors that contain higher amount of meaning information.

- The core of NLP system is a deep learning model. The model architecture may vary on the task it is built on. Some common deep architectures will be described in the next sections.

Even though deep learning architecture seems to play the central part in current NLP tasks, it is worth noting that fundamental works of NLP are still not avoidable, such as lexical scanning, parsing or semantic analysis. Especially, the famous tool *CoreNLP*, which supports core functionalities of NLP, has been incorporated in many DL-based architecture with interesting outcome observed [22-26].

3. Word Representation Models

In the book entitled Introduction to Information Retrieval [27] published in 2008, the authors explained about the techniques to exploit information various from data sources. especially in the textual form. There are two well-known classical techniques for this goal discussed in this book, including Count-Vectorization or Bag- of-words (BOW) [14], and the weights of Term Frequency - Inverse Document Frequency (TF- IDF). These two methods, in particular TF-IDF weights, are proven effective in determination of important keywords in documents. However, they cannot reflect the information of word positions in the documents and hardly convey the semantics of the words as well as the whole documents.

Word	Number	/	"am"
а	1	- /1	L o .
able	2	2	0
am	3 ←	→ 3	1
		$ \cdots $	
member	621	621	0
		\	
zebra	1000	1000	٥.

Figure 4. Representation of the word "am" as one-hot vector.

Word Embedding is a technique later emerging as a more effective method for word representation. This term was firstly coined by Yoshua Bengio in the famous paper entitly "Neural Probabilistic Language Models" [28] published in 2003. It recommended that a word vector can "embed" the semantics of words in a numerical vectors to let them be processed effectively by machines. Inspired by those idea, a number of word embedding techniques were then reported as *Word2vec* [29], GloVe [30], *fastText* [31], ELMO [32] and BERT [33]. In general, a word embedding technique should fulfill the following conditions.

- There is only one unique representation per word, i.e., two different words should be represented by two different vectors.

- Two similar words, in terms of their semantic meaning, should be represented by two similar vectors, in terms of their distance in the embedding space.

3.1. Word Representation by One-hot Vector

One-hot vector perhaps is one of the earlies technique to encode *categorical* data items as numerical vectors. Basically, a one-hot vector is a binary vector whose dimensional values are only of 0 or 1. Particularly, there is only one dimension has the value of 1 in a one-hot vector, whereas the rest are of 0. Based on that technique, one can represent every word in a text document as a one- hot vector. For instance, with a sentence of "*I am a member of URA research group*", the word *am* can be represented as a one-hot vector as illustrated in Figure 4, whose number of dimension is exactly the vocabulary size of the corresponding language.

Thus, one-hot encoding can be employed to convert any word in a dictionary into a form of numerical vector. Therefore, this technique was used in many NLP and other machine learning models, especially in the case that the vocabulary size is relatively small. Obviously, this technique fulfills the requirement that different words should be represented as different vectors. However this technique still suffers from the following drawbacks.

- When working with a large vocabulary size, this technique tends to generate very sparse high-dimensional vectors, most of whose dimensional values are of 0.

- More importantly, it can be undeniably observed that the Euclidean distance between any pair of one-hot vectors is constantly of V2. This prevent one-hot vectors from representing the difference in semantics of the words.

3.2. The Word2vec Technique

Word2vec is one of the popular techniques in the Natural Language Processing field. It was publicly announced in 2013 by a group of researchers led by Tomas Mikolov and has been registered for protection of the mode of the invention [29]. Based on AutoEncoder [34], Word2vec has solved the problems related to context meanings of the AutoEncoder model by transforming each word of the corpus into a vector based on their contextual information in that corpus. Therefore, the model is able to learn so as to produce a similar vector for those words that share the same contextual information. The contextual information of a focus word is a window containing words on the left side and right side of the focus word, which are called context words. The size of the window, denoted by k, represents k words on the left side and kwords on the right side of the focus word.

Two main training techniques of *Word2vec* are *CBOW* and *Skip-gram*.

CBOW (Continuous Bag of Words)

The idea behind the CBOW model is that it predicts the focus word vector based on the context words collected from a *k*-size window in which *k* is finite. Given a focus word w_t at the position *t* inside the sequence, the context words contains ($w_t - m, \ldots, w_t - 1, w_t + 1, \ldots, w_t + m$) surround the focus word w_t in the window size of *m*.

Figure 5. A general CBOW model.

The CBOW model can be generalized as illustrated by Figure 5. In Figure 5, C is the number of context words while V is the size of vocabulary and the hyperparameter N is the number ofnodes in the hidden layers where N is relatively small compared to V. Every node of the hidden layer is fully connected to the nodes of the previous layer.

When the CBOW model is trained with a large corpus, we will gain a good representative matrix w with size $V \times N$ when the training process converges. From then, with an arbitrary one- hot vector T with size 1 X V, we can get an embedding vector E with size 1 X N based on the product operation of $E = T \times w$.

For example, with this one-hot vector for the word "am":

$$x_{am} = \begin{bmatrix} 0\\0\\1\\\vdots\\0 \end{bmatrix}_{V \times 1}$$

And matrix $W_{V \times N}$ shown below

$$W_{V\times N}^{T} = \begin{bmatrix} 2.4 & 1.6 & 1.8 & \dots & 3.2 \\ 2.6 & 1.4 & 2.9 & \dots & 6.1 \\ \vdots & \vdots & \vdots & \ddots & \vdots \\ 1.8 & 2.7 & 1.9 & \dots & 1.2 \end{bmatrix}_{N\times V}$$

We can perform matrix multiplication $v'_{am} = W' \times x_{am}$ and receive the resulting matrix as below:

$$v_{am}^{T} = \begin{bmatrix} 2.4 & 1.6 & 1.8 & \dots & 3.2 \\ 2.6 & 1.4 & 2.9 & \dots & 6.1 \\ \vdots & \vdots & \vdots & \ddots & \vdots \\ 1.8 & 2.7 & 1.9 & \dots & 1.2 \end{bmatrix} \times \begin{bmatrix} 0 \\ 0 \\ 1 \\ \vdots \\ 0 \end{bmatrix}$$
$$= \begin{bmatrix} 1.8 \\ 2.9 \\ \vdots \\ 1.9 \end{bmatrix}$$

As we can see, vector v^{T} has the dimension N which is relatively small compared to V. This vector is no longer considered as a sparse vector since all of its values are now different from 0. Moreover, the training procedure of the CBOW model also helps create embedding vectors with

closer distances for the words that frequently appear together in the context words. After the CBOW training converges, the matrix *WvXn* will be used as an embedding layer for other deep learning models specialized in NLP tasks as illustrated in Figure 3.

The skip-gram model

The skip-gram model is demonstrated in Figure 6. This model is similar to CBOW; however, the focus word is now used as the input for the model and the context word as the expected output.

4. Convolutional Neural Network for NLP

4.1. Convolutional Neural Network

Figure 6. A general Skip-gram model.

Convolutional Neural Network, known as *CNN* or *ConvNet*, is one of foundation techniques in the area of *Computer Vision*, or *Deep Learning* in general. This kind of architecture is typically used for image classification, such as the problem of facial recognition. This architecture is proposed by the famous scientist Yann LeCun, winner of the Turing award in 2018, for the problem of handwritten zip code recognition [35].

Basically, a CNN architecture consists of the following layers: *convolutional*, *pooling* and *fully connected*. In certain variants, convolutional and pooling layers can be repeated many times before feeding to the final fully connected layer, as illustrated in Figure 7.

36

Figure 7. An illustrative CNN architecture.

In the typical Feedforward Neural Network, the layers directly connected via a weight vector *W*, known as fully connected layer or *a*ffine *layer*. In constrast, in the convolutional layer, the layers are connected via the convolution mechanism. That is, each neural of the next layer connects to a local region of the previous layer via a *convolution window*, or *filter*. During the training process, the CNN network will automatically learn the appropriate weights of the filters.

After the convolutional layer is the *pooling layer*, or *subsampling layer*. The objective of this layer is to standardize the output vectors of the filters, to make them have the same dimension space using a *pooling window*. In addition, by only selecting a value in each pooling window as the next output, the number of parameters to be trained would be significantly reduced, as compared to a corresponding MLP network with the same number of neural nodes.

Figure 8 illustrates the computational process in the convolutional and pooling layers of a CNN network. The output results from the each filter will be eventually concatenated, producing the final *feature map*, which can in turn be used as input for the next similar process, or fed to the a fully connected layer to get the final prediction of the model.

4.2. CNN for NLP Tasks

The CNN network is initially intended to work with images represented as matrices. Thus, in order to be applied with NLP tasks, the original textual documents needed to be represented as matrices as well. With the Word Embedding technique discussed previously, each word in a document can be encoded as vector of the same dimension. Then, a document can be formed as a matrix, on which the CNN can be applied as depicted in Figure 9. In this example, the problem of Sentiment Analysis is picked as a case study, adapted from the work published in [36], which is considered as a pioneered work that applied CNN for NLP. Interested readers can further refer to this paper for the way to select suitable *hyperparameters* when implementing the model.

For more details, we can consider the architecture in Figure 9 as 5 parts, namely #sentence, #filters, #featuremaps, #1-max and #concat-1max, whose information is given as follows.

sentence

This is the input of the system, in this case is a sentence of 7 words: "*The film contains a few funny bits*". Assuming that the embedding dimension is 5, the sentence is then represented as a 7 X 5 matrix.

filters

Initially, CNN is used for Computer Vision applications, whose input is normally a 2D or 3D images/objects. Thus, their filters are also organized as 2D matrices or 3D cubes to reflect this dimensional characteristic. However, for textual data, the input is naturally organized as a 1D series of word. In that case, the filters adopted by a NLP-intended CNN would also be adapted accordingly. To be more precise, the number of columns in the filter will be the same of the size of the embedding word vector, meanwhile its rows are used to reflect the concept of *n*-gram of text data. In this example, the row for each filter will be either in (2,3,4), corresponding to the concepts of bigram, trigram and 4-gram of classical NLP. The are two filters for each kind, eventually making 6 filters for whole system.

featuremap

In this context, the feature maps are the matrices generated once we perform the convolutional operation between the *#filters* on the *#sentence*. Since the columns of the filters are the same with the dimension of the embedding space, each feature map is then a column matrix whose size is varied depending on the filter size.

1-max

This is in fact corresponding to the pooling layer in the standard CNN architecture, where the maximal value in each column vector of the feature map will be selected for further processing. As a result, we have a set of 6 maximal numbers from 6 column vectors.

concat-1-max

In this step, the results from *#1-max* are concatenated together, making another column vector of 6 element, which is then connected to a *softmax* layer using the fully connected mechanism. The result of this *softmax* layer is treated as a binary classification of sentiment opinion, e.g *positive* or *negative*.

Figure 8. The generation of a feature map in a CNN network via convolutional and pooling layers.

Figure 9. Using CNN to perform the task of Sentiment Analysis.

In qaddition, CNN is also considered for information modeling at character level. For instance, Santos [37] va Labeau [38] had successfully leveraged this work for the problems of NER and POS-tagger, respectively.

5. Recurrent Neural Network for NLP

5.1. Sequence Data

Natural language data is an ordered sequence of data. Unlike the traditional data type where the patterns are unordered and independent of each other, with natural language data, the order of occurrence of the data patterns also carries certain information. In text data, the order in which words appear in a text plays a very important role in conveying the meaning of a sentence or paragraph.

Feed-forward networks with fixed input data cannot solve the problem with arbitrary length sequence data. However, sequence data can be transformed (split) for using on input-only architectures by taking a fixed amount of k samples of previous consecutive data as input. Models that approach this direction are classified as *auto regressive models*. In general, a generic k-degree auto regressive model can be understood as a mapping f:

$$\dot{y}i = f(Xi, yi-1, yi-2, ..., yi-k)$$
 (1)

where x_i is the existing observation, y_i is the sequence value at time i, y_i is the predicted value at time i, y_i is the sequence value at time i, k is the model degree. With the above approach, we temporarily solve the problem of vary data length. However, there are still many problems that make MLP networks unsuitable for sequence data as follows.

- The MLP model is not yet able to remember the state from previous data to support decision making. In fact, it still depends entirely on the input. In case it is necessary to remember data at a length greater than k- degree of the model, the feed-forward network will not be able to make an accurate prediction. Indeed, the way in which the above regressive model derives its data from earlier samples in the sequence is entirely up to the assumptions of the network designer.

- The number of parameters is very large: when using a fully connected layer, the number of parameters of a layer will be equal to the product of the input dimension and the output dimension. The large number of parameters also makes the model take up a lot of resources both in terms of memory requirement and training time.

- The model is not capable of sharing weights between steps (fully connected layers) and uses a large number of parameters specific to each input on every layer.

Figure 10. The conceptualization of an RNN.

5.2. Recurrent Neural Network

In 1986, Rumelhart and his colleagues published a research paper entitled" Learning internal representations by error propagation" [39]. In the study, a classic network architecture for processing sequence data is presented, called a *recurrent neural network*. Basically, a recurrent neural network is a neural network architecture in which the state of the model at the previous step is used as the input of the current step. In other words, a recurrent neural network model behaves in a way that maps the input data and the previous state of the model to output data, as shown in Figure 10.

Figure 11. Sequence data processing with RNN.

With a traditional feed-forward neural network, data are only passed in one direction, computation and output results are encapsulated in one phase and based entirely on input data (i.e. no loops exist). We need to clarify that the loop here does not create an infinitely repetitive computation cycle, but only uses data from the precomputation phase as input to the current phase. More specifically, we can "unfold" the loop to provide a more specific computational architecture when passing sequence data to the network. With a recurrent neural network, the information from the previous transmission is saved (in the hidden state) for the current computation, creating a loop on the computation graph. In other words, the hidden state acts as a memory of the recalling neuron layer. This is especially useful when dealing with time-series data, where the same calculation logic (same calculation and set of weights) can be applied to each data point in the series, preserving information from previous points. while preserving sequence information. Figure 11 illustrates how RNNs process sequence data.

Mathematically, all calculations in an RNN are presented in (2a) - (2c).

$$(a_0 = 0 \tag{2a})$$

$$\begin{cases} a_i = f(\mathbf{W}_{ax} \cdot x_i + \mathbf{W}_{aa} \cdot a_{i-1} + \mathbf{b}_a) \quad (2b) \end{cases}$$

$$\int \hat{y}_i = g(\mathbf{W}_{ya} \cdot a_i + \mathbf{b}_y) \tag{2c}$$

where

• a_i is the hidden state of the model and $a_0 =$ 0 is assumed the initial state.

- \hat{y}_i is the output of corresponding *i*-th step.
- x_i is the input of corresponding *i*-th step.

• *f* and *g* are the appropriate activation functions. Usually, we choose f(x) = tanh(x) or f(x) = ReLU(x) and g(x) = sigmoid(x) or g(x) = softmax(x) according to the design method and problem requirements.

- W and b are model weights
- W and b are model weights

- \mathbf{W}_{ax} is the matrix of linear mapping which transforms *x* to a part in state *a*.

- Waa is the matrix of linear mapping which transforms old state a to a part in new state a.

- **b***a* is the bias of transformation from old state *a* to a part in new state *a*.

- Wya is the matrix of linear mapping which transforms current state a to the output y.

- **b***y* is the bias of transformation from current state *a* to the output *y*.

5.3. Long Short-Term Memory Network

Even though the recurrent neural network is theoretically a simple and powerful model, it is difficult to learn properly due to a limit to capture long-term dependencies, caused by these two well-known issues in training a model: vanishing and exploding gradient [40]. The vanishing gradient will become worse when a *sigmoid* activation function is used, whereas a *Rectified Linear Unit* (ReLU) can easily lead to an exploding gradient. Fortunately, a formal thorough mathematical explanation of the vanishing and exploding gradient problems was represented by Bengio et al., [41], analyzing conditions under which these problems may appear.

To deal with the long-term dependency problem, a developed version of RNNs was introduced by Gers and Schmidhuber and Cummins in 2000, called Long Short-Term Memory (LSTM) [42]. LSTMs has overcome the limitations of RNNs and delivered more accurate performance by using a hidden layer as a memory cell instead of a recurrent cell (see Figure 12). In the standard LSTM model, processing information is more complicated when modules containing computational blocks are repeated over many time steps to selectively interact with each other in order to determine what information will be added or removed. This process is controlled by three gates namely input gate, output gate, and forget gate. Controlling the flow of information inside an LSTM model can be described as the following (3a)-(3e) mathematical equations.

Figure 12. The structure of an LSTM cell.

$$i = \sigma(\mathbf{W}_i x_t + \mathbf{W}_{hi} h_{t-1} + \mathbf{b}_i)$$
(3a)

$$f = \sigma(\mathbf{W}_f x_t + \mathbf{W}_{hf} h_{t-1} + \mathbf{b}_f)$$
(3b)

$$o = \sigma(\mathbf{W}_o x_t + \mathbf{W}_{ho} h_{t-1} + \mathbf{b}_o)$$
(3c)

$$(\mathbf{C})_{t} = (\mathbf{C})_{t-1} \otimes f + tanh(\mathbf{W}_{C}x_{t} + \mathbf{W}_{hC}h_{t-1} + \mathbf{b}_{C})$$
(3d)

$$h_t = o \otimes tanh((C)_{t-1})$$
(3e)

In (3a)-(3e), it, ft, ot, (C)t, ht denote input gate, forget gate, output gate, internal state, and hidden layer at t-th step, respectively. xt is the input of corresponding *t*-th step. Next, W_i , W_f , W_o , W_c , and b_i , b_f , b_o , and b_c represent the weights and bias of three gates and a memory cell, in the order given. Concretely, the activation function sigmoid (a) helps an LSTM model to control the flow of information because the range of this activation function varies from 0 to 1 so that if the value is 0 then all of the information will be cut off, otherwise the entire flow of information will pass through. Similarly, the output gate will allow information to be revealed appropriately due to the sigmoid activation function then the weights will be updated by the elementwise multiplication of output gate and internal state activated by nonlinearity tanh function. With the pivotal component is the memory cell accommodating three gates: input, forget, and output gate, LSTMs has overcome limitations of RNN, enhancing the ability to remember values over an arbitrary time interval by regulating the flow of information inside the memory cell. Therefore, LSTMs possess a capacity to work tremendously well on learning features from sequential data

such as documents, connected handwriting, speech processing, or anomaly detection [43].

Later, a simpler version of LSTM, known as GRU [44], was also introduced. GRU uses no hidden memory and fewer gates than LSTMs does. As a result, GRU has a faster training process, consumes less memory while maintains high performance and can compete with LSTMs in some cases.

5.2. BiLSTM and NLP Applications

Figure 13. A CNN-BiLSTM architecture for NER task.

RNN and its upgraded versions like LSTM and GRU can handle sequence data well in NLP problems. To enrich information encoded in each step, NLP applications often use а bidirectional mechanism, known as **Bidirectional** LSTM (BiL-STM) or Bidirectional GRU (BiGRU), in which data is processed across two opposing LSTM or GRU networks. The result at each step of these two opposite networks will be concatenated to the final representation of each step. In addition, because CNN is very powerful in feature extraction, RNN-based architectures often combine with CNN to extract features from the original text before racing to be processed in RNN layers. Figure 13 illustrates architecture of using CNN-BiLSTM for named entity recognition [45]. In addition, the same architecture is also used for sentiment analysis [46], PoS tagging [47], text classification [36] problems.

6. Sequence-to-sequence Model and Attention Mechanism

6.1. Sequence-to-sequence Architecture

Sequence-to-sequence (seq2seq) [48] is a deep-learning architecture initially devised for machine translation. Its intuition comes from an observation such that in order to translate a text, human would first read some parts of the text and then start to do the translation. NLP researchers also employ that idea into designing a structure dubbed as sequence-to-sequence.

Figure 14. An example of a sequence-to-sequence model.

Basically, sequence-to-sequence model takes the design principle of comprising 2 components, an encoder and a decoder, as illustrated in Figure 14. For a vanilla sequenceto-sequence model, both the encoder and decoder are recurrent neural networks, but in order to capture longterm dependencies, we could choose LSTM or GRU instead. In general, the encoder has a function to digest and understand the input text as well as encode the information into a fixed-shape hidden state. Output sequences are generated by using the method of token-by-token, which means the previously created token will be the next time step input token. The decoder combines two source inputs encoder hidden state and current input token to consider the probability of generating the next word. The process of generating output will stop if the sequences

touch the maximum length of the result or the current token is a special "end" token.

Encoder

For an input sequence x_1, \ldots, x_T , the encoder will read and print out a fixed-shaped vector **c** taking the context into account. We assume that the input sequence is $X_1 \cdots x_T$ known that **x**t is the tth token and. **h**t is the hidden state of time step t. Then, let us express f as the computation of an RNN unit as follows.

$$\mathbf{h}_t = f(\mathbf{x}_t, \mathbf{h}_{t-1}) \tag{4}$$

Eventually, after passing through all the tokens in the sequence, the encoder transforms the whole sequence into a context vector.

$$\mathbf{c} = q(\mathbf{h}_1, \dots, \mathbf{h}_T) \tag{5}$$

Usually, q function takes the final hidden state of encoder into context variable c. In order to make the encoder has better performance, instead of using unidirectional RNNs which just focus on previous hidden states, we can use bidirectional networks to consider both sides the previous and after ones.

Figure 15. A simple attention model.

Decoder

As mentioned in the last passage, an encoder converts the input sequence into a context vectorc. Hereafter, it is time for the decoder to evaluate the conditional probability $P(y_t, y_1, ..., y_{t-1}, c)$ given the context vector c and past decoded to- kens $y_1, ..., y_{t-1}$.

At any time-step t, decoder takes the output token y_{t-1} , context variable c and previous decoder hidden state s_{t-1} then transforms them into current decoder hidden state as below

$$s_{t'} = g(y_{t'}-1, c, s_{t'}-1)$$
 (6)

Note that g is a transform function. After gaining current decoder hidden the state, sequence-to- sequence will put effort into estimating the conditional probability by applying a softmax operation on output layer, which is a fully-connected layer to transform final hidden state. Then, the final probability is calculated by multiple probability of each word along time steps.

$$p(y_1, \dots, y_m \mid x_1, \dots, x_n) = \prod_{t=1}^m p(y_t \mid c, y_1, \dots, y_{t-1})$$
(7)

6.2. Attention Mechanism

Sequence-to-sequence model causes the RNN problems such as vanishing gradient excessively severe. Although the encoder and decoder can take LSTM or GRU forms, the performance still deteriorates for input with a length approximating 100 tokens, which is sorely popular in tasks such as machine translation or text summarization.

Besides, in prominent tasks such as machine translation, there are a number of alignments between the output and input. That is, some words in the output could be linked to some from the input sequence. For instance, translating from "And the programme has been implemented" (English) to "Le programme a et e mis en application" (French), phrases such as "programme" and "mis en application" shall be mapped to "pro- gramme" and "implemented" in the respective order.

Bahdanau et al., [49] proposed an attention mechanism to implement that concept. The input of the attention scheme is a query vector q. For a query, attention returns an output related to the memory consisting of key and value pairs $(k_1, v_1), ..., (k_n, v_n)$.

We will start to derive the output of the attention. For each key $k_1, ..., k_n$, we perform the *dot product* with the query to learn the corresponding value. This operation demands that the query andthe key have the same dimension d. For query and key $q, k \in \mathbb{R}^d$,

Figure 16. Sequence-to-sequence model with attention.

o compute operations effectively, we often employ matrix computation. Assuming that input attention has *n* queries and *m* key-value pairs. Length of queries and key is d, while length of values is equal v. So, we have matrices called query Q e R^{nxd} , key K e R^{mxd} and value V e R^{mxv} . Then, the equation becomes

Additive Attention In general, we may utilize additive attention as the attention scoring function when queries and keys are vectors of various lengths. For query and key $q \in \mathbb{R}^{q}$, k $\in \mathbb{R}^{k}$,

$$\alpha(\mathbf{k},\mathbf{q}) = \mathbf{v}' \tanh(\mathbf{W}_k \mathbf{k} + \mathbf{W}_a \mathbf{q}). \quad (10)$$

where $W_k \in \mathbb{R}^{hxk}$, $W_q \in \mathbb{R}^{hxq}$ are two weight parameters corresponding to key k, query q respectively and $w_v \in \mathbb{R}^h$.

6.3. Enhancement of seq-to-seq Model by Attention

In Figure 16 is an example of using sequenceto-sequence with attention mechanism for machine translation. When endeavoring to generate the next token, the

(8)

hidden representation will attend to the representations of input tokens. As it can be seen from Figure 16, with a view to obtain the attention scores, the system will compute the dot products between the representation of "he" with those of the source input. Subsequently, the computed scores will play a role as the weights to coalesce the hidden representations of input tokens to form the attention output. Eventually, this output will be employed to determine the logits to generate the output token.

7. Pre-trained Language Models

7.1. Language Models

In NLP, language models are models that can assign probabilities for a sequence of words or a sentence. In addition, language models can infer *likelihood* for a particular word (or sequence of words) from a preset input sequence. In mathematics methodology, the probability assignment for a word sequence can be modeled by chain rule in Equation 11:

$$P(w_1, w_2, ..., w_n) = \prod_{i=1}^n P(w_i | w_{1:i-1})$$
(11)

where *wi* denoth the *i*-th word in a sentence.

7.2. Language Model Construction with RNN

In classical approaches, probability assignment is usually based on *n*-gram Markov model [50]. However, with the help of Deep Learning, recent approaches choose RNN architectures to train language models because of their outperformanced leaning capability on large dataset. Moreover, language models trained from RNN can be efficiently used as pre-trained language model for other NLP tasks as described below.

RNN works by using probabilities of previous words to generate probability for the next word. The generated word is then used as input of RNN to produce the next word until the endof-sequence word is produced as depicted in Figure 17. Finally the probability of the whole sequence is computed as in Equation 11.

Figure 17. Language model with RNN.

Let "Today I go to school. Tomorrow I go to school too" be an input sequence for RNN. It is supposed that the corpus only contains words in this input sequence, then each word in corpus is a 1 x 7 vector in one-hot presentation. For example x^{0} is a zero vector of size corpus length, which is 1x7 in this case. The first hidden state a^{0} is a zero vector of any particular size based on our decision, which is 1 x 5 in this example. Waa is a 5 \times 5 matrix and Wax is a 7 \times 5 matrix so $a \times W_{aa} + x \times W_{ax}$ is a 1 x 5 matrix. The 5×7 matrix W_{av} is then used to resize this hidden state to desired output size 1 x 7. The result is fed into softmax activation function to produce output vector y. This output acts as a probability distribution for each word in corpus. Finally, the appropriate loss criteria based on y and y is used to update model's weights. The whole procedure is illustrated in Figure 18.

Figure 18. Detailed language model training procedure at one timestep with RNN.

7.3. Pre-trained Language Models

Since 2018, many state-of-the-art NLP researches are based on pre-trained language models such as ELMo [32], OpenAI GPT [51] or ULMFit [52]. There are two existing strategies for applying pre-trained language representations to downstream tasks as follows.

- *Feature-based*: This strategy includes pretrained representations as additional features (e.g., ELMo).

- *Fine-tunning*: This strategy introduces taskspecific parameters and fine-tune the pre-trained parameters (e.g., OpenAI GPT, ULMFit).

Figure 19 illustrates a representative situation using pre-trained language models for downstream task using UMLFit. This is a language model with many LSTM layers stacked on to each other. This model is first trained with a very large dataset then fine-tuned on domain dataset. Finally, with a specific target application dataset, the model with pre-trained weights is used as an embedding layer to represent input values as vector. These representation vectors is then used as input for other downstream task such as classification by SVM [53].

Figure 19. Using pre-trained language model of UMLFit [52].

Limitation of these language models is unidirectional manner because they restrict the power of the pre-trained representations. For example, OpenAI GPT uses left-to-right architecture whereas ELMo concatenates forward and backward language models. In 2018, BERT [33] was introduced, which based on Transformer architecture [54] became a more comprehensive solution.

7.4. Transformer Model

Figure 20. Transformer architecture [54].

RNN units with their counterparts such as LSTM and GRU have established state-of-theart results in multiple sequence modeling tasks. Combined with attention, the performance of problems such as machine translation and text summarization has been upgraded to a new level. Nonetheless, there is still one obstacle with those architectures, which is embedded in the sequential nature of the input and output. The incapability to parallelize the computation has caused a huge overhead in computation time. Transformer's authors proposed an architecture dubbed as Transformer removing the recurrence or convolutional layers. Instead, they suggested that solely relying on attention is the key to achieve parallelism. Self-attention is a core mechanism that connects distinct places of a single sequence to compute a representation of it. Almost NLP tasks such as reading comprehension or learning task-independent sentence representations have all been effectively utilized with self-attention.

Seq2Seq Paradigm in Transformer

Furthermore, at first sub-layer, instead of fully attending to the whole sequence in the input, for the time step t° , the decoder only performs attention from the current token to tokens $1, \ldots, t-1$. Thanks to this masking method and the output tokens are offset by one place, the predicted token for position *i* can only be based on the known outputs at locations less than *i*.

Self-attention

There is a key factor to differentiate between the "original" attention and self-attention. Whereas attention evaluates the alignment of a token to its previous ones in a recursive manner, self-attention allows one to fully attend to all of the tokens in the sequence, making parallelism possible. In particular, for all keys, queries and values are packed into matrices K, Q and V. The attention scoring function used is scaled dotproduct attention. After calculating scoring, we divide by \sqrt{d} and then apply softmax function to show attention distributions on determined values.

Attention(Q, K, V) = softmax(
$$\frac{QK^{I}}{\sqrt{d_{k}}}$$
)V (12)

The scaling factor $\frac{1}{\sqrt{d_k}}$ is to reduce the effect d_k

of the dimension to the final output. The reason why attention function is chosen with scaled dot- product but not addictive attention is that the for- mer is much faster and has space-efficient.

Multi-Head Attention

One interesting result of Transformer [54] is that they found it is advantageous to conduct attention multiple times with respect to a wide variety of linear projections. Multi-head attention allows the model to simultaneously attend to input from several representation aspects at various locations. Whilst using a single attention head, model will learn average of all these aspects, which not detailed. The detailed equation is as follows.

MultiHead(Q, K, V) = Concat(head₁, . . . , head_h) W^{O}

where $head_i = \text{Attention}(QW^Q, KW^K, VW^V)$ Note that $W_i^Q \in \mathbb{R}^{d_{model} \times d_k}, W_i^K \in \mathbb{R}^{d_{model} \times d_k},$ $W_i^V \in \mathbb{R}^{d_{model} \times d_v}$ are parameter matrices for projecting queries, keys and values. In particular, $d_k = d_V = d_{model}/h$ where *h* is the number of heads. *Positional Encoding*

In sequential data, positional information bears an important effect to the semantics of the sequence. Since Transformer is not estab-lished on recurrence nature, it must encode an- other method to take into account that kind of information. There are several learnt and fixed positional en- coding types to choose from. Specifically, Trans- former authors took advantage of sinusoidal sig- nal, in which they transported the positions into sine and consine functions. The positional encod- ings and embeddings layers have the same dimen- sion, thus they could be added together. Accord- ing to the experiment of authors, the first method second which use sinusoidal signal gain the nearly identical results.

 $PE_{(pos,2i)} = sin(pos/10000^{2i/d_{model}}) PE_{(pos,2i+1)} = cos(pos/10000^{2i/d_{model}})$

where pos stands for position and i is the dimension. That means each dimension in the encoded vector would represent a sinusoidal wave.

7.5. Transformer-based Language Models

Transformer model has resulted in the development of a large number of pre-trained language models. Some outstanding models can be mentioned as GPT-2 [55], BERT [33] and Trans- former XL [56]. GPT-2 employs layered Trans- former decoder layers. In the meanwhile, BERT employs Transformer encoder layers, and Trans- former XL provides a recurrent decoder architecture based on the Transformer decoder.

These days, perhaps the most commonly utilized Transformer-based architecture in NLP

tasks is BERT. The version landscape of BERT is depicted in the Figure 21.

Figure 21. Variants of BERT [57] [11].

BERT's overall architecture is shown in Figure 22, which comprises a stack of Transformer encoder's layers. Furthermore, BERT uses two training techniques during pre-training steps, whose details are as follows.

Masked LM (MLM)

The concept is straightforward: Masking 15% of the words in the input with a [MASK] token at random, then running the full sequence through the BERT attention-based encoder and forecasting just the masked words given on the context provided by the other non-masked words in the sequence. This basic masking strategy, however, has a flaw: the model only tries to predict the correct tokens when the [MASK] token ispresent in the input, while we want the model totry to predict the proper tokens regardless of the masked token's presentation in the input. To ad dress this issue,

15 percent of the tokens chosenfor masking were:

- 80% of the tokens are actually replaced with the token [MASK].

- 10% of the time tokens are replaced with a random token.

- 10% of the time tokens are left unchanged.

During training, the BERT loss function only considers masked token predictions and ignores non-masked token predictions. As a result, the model converges far more slowly than models that are left-to-right or right-to-left.

Next Sentence Prediction (NSP)

The BERT training procedure also uses next sentence prediction to understand the relationship between two sentences. For jobs like question answering, a pre-trained model with this level of knowledge is useful. During training, the model is given pairs of sentences as input and is taught to predict if the second sentence is the same as the next sentence in the original text. BERT uses a specific [SEP] token to separate sentences. Themodel is fed two input sentences at a time during training, as follows:

50% of the time the second sentence comesafter the first one.

50% of the time it is a random sentence from the full corpus.

BERT is then required to predict whether the second sentence is random or not, with the assumption that the random sentence will be disconnected from the first sentence. To determine if the second phrase is connected to the first, the entire input sequence is passed through a Transformer-based model, the final hidden state of the [CLS] token is transformed into a 2×1 shaped vector by using a simple classification layer, and the probability of IsNextSentenceLabel is calculated by *softmax* - an activation function.

Knowledge is useful. During training, the model is given pairs of sentences as input and is taught to predict if the second sentence is the same as the next sentence in the original text. BERT uses a specific [SEP] token to separate sentences. The model is fed two input sentences at a time during training, as follows:

- 50% of the time the second sentence comes after the first one.

- 50% of the time it is a random sentence from the full corpus.

BERT is then required to predict whether the second sentence is random or not, with the assumption that the random sentence will be disconnected from the first sentence. To determine if the second phrase is connected to the first, the entire input sequence is passed through a Transformer-based model, the final hidden state of the [CLS] token is transformed into a 2 X 1 shaped vector by using a simple classification layer, and the probability of IsNextSentence-Label is calculated by softmax - an activation function.

Both Masked LM and Next Sentence Prediction are used to train the model. This is to minimize the combined loss function of the two strategies. The following are some applications of BERT's usage in common NLP tasks:

Text Summarization: the most commonly used model is BERTSUM [58] to produce

summary by highlighting or identifying key sentences.

Text Classification: one of the typical Text Classification is Sentiment Analysis - labeling a sentence with positive, negative or neutral emotions.

Question Answering: the input is a question related to a given text and BERT is asked to mark the answer by identify two vectors marking the beginning and the end.

Named Entity Recognition: input is a passage and the model is requested to find the different types of entities (*Person*, *Organization*, *Date*, etc.) that appear in the source.

Figure 22. BERT general architecture [33].

8. Applications of DL Models in NLP

Since introduced, those aforementioned models have been applied successfully in various domains, including NLP. Remarkable applications of those models, together with their advantages and disadvantages, can be capture at the quick glance as follows.

Conventional RNN models calculate their output based on the recent input and their memory calculated from the previous steps. By reusing weights on every calculation step, RNN

48

is known to be deep in terms of time with a limited number of parameters. The nature of RNN makes it suitable for time series data processing applications. However, these models only have the "memory of goldfish" and can only perform well with short history context.

To handle short-term memory and vanishing gradient problems in RNN, LSTM (Long shortterm memory) as an extended version of RNN with gating technique to control information flow over its inferencing steps and this deep learning model become commonly used in timeseries data forecasting [59-61], speech recognition [62, 63], robotic tasks [64, 65] and NLP tasks including text generation [66], text classification [67], word prediction, next sentence selection, and sentence topic prediction [68, 69]. However, in the above applications, LSTM still suffers from long-term dependency difficulty. Tackling parallelism in RNNs, Ashish (2017) [54] designed a new deep learning sequence-to-sequence architecture that fully replaced RNNs with atten- tional layers (self attention and cross attention), shortening training time and better representing the relationship of data within the input and generated sequences. Transformer and its variants are mostly used in machine translation [70-72], summarization [73, 74], text generation [75] or question answering [76-78], etc. This model architecture has a limitation of its input sequence length, leading to text chunking during inferencing and causing the disruption of information representation.

BERT was built on the encoder of Transformer architecture [79] and trained with mask and next sentence prediction tasks, thus can "understand" text sentences and provide a strong base model for downstream tasks. In applications that need representation of input sequence such as sentiment analysis [80, 81], intent prediction [82, 83], POS Tagging [84], named entity recognition [85-88], event extraction [8991], relation extraction [88, 92-94]. BERT encodes the input embedding sequence with selfattention mechanism in a bidirectional manner, which means a vector at any position can "see" all other vectors and represent its meaning based on the global context without step-by-step projection. This mechanism is the strength of BERT, but it is also a constraint stopping BERT to scale up in terms of sequence length because of the memory cost of storing matrices and computational cost of dot products during attention calculation.

9. Conclusion

In the era of the Fourth Industrial Revolution, digital data have been incrementally generated in all domains in an automatic manner, calling for intelligent systems to effectively process them for making useful information and knowledge for human beings. As natural languages are still the main channel for communication in human societies, Natural Language Processing has emerged as one of the important approaches to response such a call. Especially, with the advancement of Deep Learning techniques, NLP researchers find for themselves powerful tools to handle enormous textual computer-generated data, which bring NLP tasks to new breaking results.

In this paper, we have introduced an overall roadmap about the modern approaches in NLP. As the scientists in this area never cease to explore novel research directions for practical application, currently there are several ongoing interested works still under investigation for further processing and extentions, remarkably as follows.

- *Natural Language Generation*: This approach aims at generating natural language from structured representation or even nontext data, e.g. images. It can be considered as one of the most advanced achievement of AI in NLP. Intered readers can further read related works at [95, 96].

- Opposite to Natural Language Generation, *Natural Language Understanding (NLU)* converts text into machine-understandable formalism for further processing in downstream tasks. Recently, this work has been attracted much attention in chatbot development, such as [97-99]. - *Question-Answering*: It can be considered as a classical topic in NLP. However, with the emerging of DL models, advanced training methods such as zero-shot training has been applied with positive result [100-102].

- *Machine Reading Comprehension*: It is similar to NLU, however more focusing on reading long narrative. Similar to NLU, zero-shot training with deep pre-trained models have been proposed with remarkable results reported [103-105].

- Recently, *Graph Neural Network* (GNN) has been emerged as a extremely suitable approach for processing graph-based data. As semantic graph generation from textual data has been investigated for a long time, using GNN for NLP promises a very potential direction for many related tasks [106-108].

- Using *Pointer Generator Network* (PGN) for summarization [109]. Perhaps PGN is one of the most recent techniques for improving *seq2seq* model to handle the *out- of-vocabulary* problem. The combination of Transformer/BERT and PGN promises much room for exploration in this direction.

- Using *memory network* as a the next generation of deep neural networks [110]. It is another direction to manipulate the hidden memory of recurrent networks more effectively. One can consider it as counterpart of *push-down automata* in the ANN world.

- Developing DL-based models such as *Variational AutoEncoder* (VAE) for topic modeling [111]. Up to now, LDA-based methods have still been considered the most appropriate approach for the problem of topic modeling. However, traditional techniques of this approach suffer from the scalability problem when dealing with very large training corpus. Making use of ANN-based architecture to simulate LDA process is considered as a good choice to overcome such problem.

- Developing multi-modal architecture for NLP such as *Visual Question Answering* systems [112]. This direction envisions an interesting combination of multimedia data processing, such as image and text. The attention/self-

attention techniques are then evolved as *crossattention* or *co-attention* once handling such a task, producing much inspiring results at the moment.
